

Digital Audio Fundamentals Part 2

Coding

Before we go into the basics on error detection and correction, we'd like to update our block diagram of the PCM system as shown in Fig. 11. Because the binary digits coming out from the digital encoding, processing and storage block cannot be recorded by a video tape recorder directly, a modulator is used to transform the output digits into a video signal.

The tape storage medium is not ideal; besides introducing various types of noise disturbances, drop-outs occur. Hence, an encoding scheme is employed to get a reliable reproduction. First, the output sequence produced by the source is grouped into message blocks. For the PCM-F1, each message block contains 84 binary digits. The encoder then transforms each message block into a longer one, i.e., from 84 to 128 bits. The 44 extra bits added contain no new information. Hence, they are called redundant digits. Their presence, however, makes

error detection and correction possible. In the PCM-F1, there are 84 bits in each block. Thus, there are 2^{84} possible input messages and we also have the same number of code words. Moreover, this set of 2^{84} code words is called a block code. Finally, the ratio $R = 128/84$ is called the code rate. In this case, we have about 1.5 bits coming out of the encoder for each message bit going in.

When a decoder receives an encoded sequence, it has to do three things: (1) determine if an error is made during the transmission, (2) correct the error if possible, and (3) provide information that is a close approximation of the original transmitted sequence if error correction is impossible. Meanwhile, we shall state the coding theorem, which says that the probability of decoding error can be made as small as we desire by increasing the code length and keeping the code rate less than the channel capacity. There are numerous ways to construct good long codes but in engineering, the coding and decoding scheme must be practical or ideally should be easily implemented.
